# Improved Yen-Joye's Authenticated Multiple-key Agreement Protocol

## Abstract

In this article, we propose an authenticated multiple-key agreement protocol. The protocol not only secure to against the unknown-key attack but also more efficient than the other protocols.

*Keywords:* Cryptography, key agreement, key authentication, unknown-key attack.

## 1 Introduction

Diffie and Hellman first proposed key agreement protocol to establish a session key for two parties [1]. However, the protocol was later proven to be vulnerable to the *unknown key attack* by Diffie et al. [2] because the protocol did not include any key authentication process during the negotiation between the two parties [7, 9].

In 1997, Harn first proposed the authenticated key agreement protocol [3] without using a one-way hash function [6]. In 1998, Harn and Lin proposed an authenticated multiple-key agreement protocol based on the Diffie-Hellman distribution scheme [4]. There are two main features in this protocol: it without using a one-way hash function and it enable two communication entities to share multiple secret keys.

Later, the Yen-Joye [11] indicated that the Harn-Lin protocol is not secure because an attacker can successfully forge a short-term public key pair and pass the verification equation. Then, they proposed an improved the Harn-Lin protocol to get rid of this shortcoming. However, in 1999, Wu et al. [10] pointed out that the Yen-Joye protocol is insecure and can be successfully

attacked the same way the Harn-Lin protocol is. Wu et al. then proposed a protocol to enhance the security. Nevertheless, the protocol violated the original expectation of the Harn-Lin protocol that no one-way hash function should be used in the authenticated key agreement protocol.

In this article, we shall propose a modification of the Yen-Joye protocol. The modification does not only ameliorate the security but also is more efficient than Harn's protocol proposed in 2001 [5].

## 2 Review of the Yen-Joye Protocol

In this section, we shall briefly review the Yen-Joye protocol [11]. There are two phases in the protocol. The first phase is the authentication phase where two users exchange  $n$  temporary random public keys in an authenticated way. The second phase is the key-sharing phase where the users share  $n^2 - 1$  secret keys with each other.

There are two users *Alice* and *Bob* who want to establish the multiple keys by the protocol. Here, we only describe what Alice has to do because of Bob has to do basically the same thing Alice does. Initially, the system has a large prime  $p$ , and  $\alpha$  is a primitive number in  $GF(p)$ . Alice has a long-term secret key  $x_A$  and the corresponding long-term public key  $y_A = \alpha^{x_A} \bmod p$ . Then Alice randomly generates two short-term secret keys  $k_{A1}$  and  $k_{A2}$  and computes their corresponding short-term public keys  $r_{A1} = \alpha^{k_{A1}} \bmod p$  and  $r_{A2} = \alpha^{k_{A2}} \bmod p$ , respectively. The range of  $r_{A1}$  and  $r_{A2}$  is set to be  $([p/2, p - 1])$  so that no attacker can forge the keys. Alice computes the signature  $s_A$  through  $r_{A1}$  and  $r_{A2}$  as

$$s_A = x_A - (r_{A1} \cdot r_{A2}) \cdot k_A \bmod (p - 1), \quad (1)$$

where  $k_A = k_{A1} \cdot k_{A2} \bmod p$ . Finally, Alice sends  $r_{A1}, r_{A2}, s_A, cert(y_A)$  to Bob, where  $cert(y_A)$  is a certificate for Alice's public key  $y_A$ . After receiving them,

Bob verifies them via the computation as follows:

$$y_A \equiv? (r_{A1} \cdot r_{A2})^{(r_{A1} \cdot r_{A2})} \alpha^{s_A} \pmod{p}. \quad (2)$$

If it holds, Bob establishes the multiple secret keys in the second phase. Bob can derive the session keys as follows:

$$\begin{cases} K_1 = r_{A1}^{k_{B1}} \pmod{p}, \\ K_2 = r_{A2}^{k_{B1}} \pmod{p}, \\ K_3 = r_{A1}^{k_{B2}} \pmod{p}, \\ K_4 = r_{A2}^{k_{B2}} \pmod{p}. \end{cases}$$

Here, three of the four keys can be used because of *perfect forward secrecy* [8].

Thus, three authenticated session keys can be established in this protocol.

### 3 Improved Protocol

The Yen-Joye protocol is an improvement on the Harn-Lin protocol. However, according to Wu et al., the Yen-Joye protocol is no secure than its predecessor. They pointed out the Yen-Joye protocol cannot resist the same attack that bothers the Harn-Lin protocol. The attacker can forge a pair  $\{r'_{A1}, r'_{A2}\}$  in the range  $(\lceil p/2, p-1 \rceil)$  to satisfy  $r'_{A1}r'_{A2} = r_{A1}r_{A2}$  at the probability of greater than  $1/18$ . Although Wu et al. later proposed an enhanced protocol with a one-way hash function, this improved protocol violates the original expectation from the Harn-Lin protocol that no one-way hash function should be used in the authenticated multiple keys agreement protocol. In 2001, the Harn-Lin proposed an improved authenticated multiple keys agreement protocol and claimed their protocol can eliminate the attack from [10, 11].

However, the Harn-Lin protocol is not as efficient as the Yen-Joye protocol. In this article, we propose two straightforward modifications to enhance the security of the Yen-Joye protocol. The proposed protocol can withstand the attack on Wu et al's scheme and is more efficient than [5]. First, we suggest that the pair of short-term public keys  $r_{A1}$  and  $r_{A2}$  in the generation phase

should be prime numbers. This modification can help the new scheme prevent the attacker from forging another pair  $(r'_{A1}, r'_{A2})$  because the prime numbers are unique. In addition, it can obey the original requirement of the Harn-Lin protocol that the range of  $r_{A1}$  and  $r_{A2}$  should be in  $(1, p - 1)$ . Second, we suggest that the *great common divisor* (*GCD*) of  $r_{A1}$  and  $r_{A2}$  should be equal to 1. This suggestion is to prevent the attacker from finding the factor  $q$  of  $r_{A1}$  or  $r_{A2}$ . Furthermore, the range of  $r_{A1}$  and  $r_{A2}$  will fall in the  $(\lceil p/2 \rceil, p - 1)$  as the Yen-Joye protocol proposed. Both of the modifications of on the Yen-Joye protocol can make it secure against any forge of the pair  $(r_{A1}, r_{A2})$ . Besides, our modification protocol is more efficient than the Harn-Lin protocol [5] because we only do the exponentiation computation four times, less than six times required by the Harn-Lin protocol.

## 4 Conclusion

We have proposed an improved scheme to enhance the security of the Yen-Joye protocol. We require that  $r_{A1}$  and  $r_{A2}$  should be primes or  $GCD(r_{A1}, r_{A2})$  should be equal to 1 to withstand the attack of forging another pair  $(r'_{A1}, r'_{A2})$  so that  $r_{A1} \cdot r_{A2} = r'_{A1} \cdot r'_{A2}$ . The pair  $r_{A1}$  and  $r_{A2}$  should be made unique so that no attacker can find another pair to replace them. Furthermore, the Harn-Lin protocol [5] uses six exponentiation computations, while the Yen-Joye scheme four takes only. That means the Harn-Lin protocol is less efficient.

In this article, we have proposed two straightforward modifications to withstand the forgery attack on the Yen-Joye protocol. The proposed protocol retains the original expectation on the Harn-Lin protocol that the range of the short-term public key be  $(1, p - 1)$ . Furthermore, the new protocol uses less exponentiation computations than the Harn-Lin protocol [5].
